Keywords: antibody engineering; immunoglobulin variable domains; framework 1 structure; scFv fragment; stability

## Design of the CDR graft

The AHo numbering scheme (Honegger and Plückthun, 2001b) for immunoglobulin variable domains used throughout this paper has been developed to facilitate the automated comparative analysis of antibody structures, in particular the analysis of sequence-structure relationships in the CDR regions and the analysis of antigen-antibody interactions. In contrast to other numbering schemes for antibody variable domains, such as Kabat (Kabat et al., 1991), Chothia (Chothia and Lesk, 1987; Al-Lazikani et al., 1997) and IMGT (Lefranc et al., 2003), it pays particular attention to the placement of the alignment gaps in CDRs of different lengths in such a way that structurally equivalent residues obtain the same residue numbers. As a result of this analysis of all antibody structures available in the Protein Data Bank (http://www.rcsb.org/pdb/) at the time of the analysis, we compiled tables of average solvent exposure for each residue, involvement in interchain- and interdomain- interactions and differential antigen contact probabilities for distinct antigen binding modes. We differentiate "hapten binding", denoting a binding mode where the antigen inserts deeply into the $\mathrm{V}_{\mathrm{L}} / \mathrm{V}_{\mathrm{H}}$ interface, "peptide binding", where an elongated groove facilitates the binding of linear epitopes, and "protein binding", where the hapten binding pocket is filled with CDR-H3 residues and a relatively flat binding surface facilitates the binding of structural epitopes. The aim of that study was to provide a solid structural basis for the design of CDR randomization strategies for the human combinatorial antibody library (HuCAL ${ }^{\circledR}$ ) (Knappik et al., 2000; Rothe et al., 2008).

Those results of the analysis that are relevant to the design of a CDR-graft (Honegger, 2008) are summarized as color codes in Figure S1. More information can be found on the AAAAA website (http://www.bioc.uzh.ch/antibody/). The average contribution of the different sequence positions to antigen contacts, interchain- $\left(\mathrm{V}_{\mathrm{L}} / \mathrm{V}_{\mathrm{H}}\right)$ and interdomain- $\left(\mathrm{V}_{\mathrm{L}} / \mathrm{C}_{\mathrm{L}}\right.$ and $\mathrm{V}_{\mathrm{H}} / \mathrm{C}_{\mathrm{H}}$ ) contacts (Figure S1c) was determined by comparing the solvent accessibility of each residue in the relevant complex to its accessibility in the isolated domain. The color code represents the average reduction in solvent accessibility, from white, residues not involved in the interface in any of the structures analyzed, over shades of yellow and orange, to red for residues fully buried in the interface in all structures analyzed. Projected onto a homology model or structure of an antibody scFv fragment, these antigen contact probabilities offer a more differentiated view of the putative antigen binding site than the CDR definitions of Kabat (Kabat et al., 1991), Chothia (Chothia and Lesk, 1987; Al-Lazikani et al., 1997) and IMGT (Lefranc et al., 2003) (Figure S1b).

In addition to the antigen binding interface, the $\mathrm{V}_{\mathrm{L}} / \mathrm{V}_{\mathrm{H}}$ interface is also relevant to the successful design of a CDR graft, since residue substitutions in this interface can affect the relative orientation of the two domains and thereby the topography of the antigen binding interface.

The average side chain accessibility (Figure S1d) distinguishes between residues fully buried in the individual domain (yellow), partially exposed (shades of green) or highly exposed, pointing into the solvent from exposed loop regions (blue). The fully buried residues (yellow) that make up the domain core can be divided into three groups: The packing of the upper core residues supports the CDRs, residue substitutions in this group have a high probability of affecting the CDR conformations and indirectly affect antigen affinity. The central core (blue) is a group of highly conserved residues that shield the upper core from the high diversity of the lower core. Packing of the lower core residues (green) is fairly conserved in $\mathrm{V}_{\mathrm{L}}$ domains, while in $\mathrm{V}_{\mathrm{H}}$ domains it is conserved within individual germline family, but varies between germline families and structural subtypes.

In the region of CDR-H2, this clean separation between upper core, central core and lower core breaks down. In CDR graft from a non-human antibody to the closest human homolog, this normally does not make any problems, since the packing of the lower core is conserved between the most closely related germline families of different species. It becomes a problem in grafts to a divergent $\mathrm{V}_{\mathrm{H}}$ framework subtype (Honegger and Plückthun, 2001a; Honegger, 2008). The packing interactions between the upper core residues derived from the CDR donor and the lower core residues derived from the acceptor framework have to be carefully analyzed and optimized to avoid excessive destabilization or alteration of the CDR-H2 conformation or take-off angle, leading to a major loss of antigen binding affinity. However, subtle differences in backbone conformation, side-chain orientations and core packing interactions cannot always be fully compensated by mutational change of a few contact residues, leaving some residual strain. In grafts from an intrinsically weak antibody to a highly stable one, this residual strain is masked by the stability gain imparted by the more stable acceptor framework. However, the direct comparison of grafts to acceptor frameworks of different structural subtypes (Willuda et al., 1999; Honegger et al., 2008) and grafts from an intrinsically stable framework, such as the mutationally stabilized 4G7-mut, show that if the stability of a graft fails to reflect the superior stability of a highly stable acceptor framework, it can be due to a structural mismatch between CDR donor and acceptor
framework. A graft to a more closely related, though intrinsically somewhat less stable framework may yield superior results and should be considered as an alternative.

With the exception of the mutation of Leu H12 to Asp, which was introduced solely to improve the folding efficiency of the $\mathrm{V}_{\mathrm{H}}$ domain, as discussed for 4G7-mut, all mutations in 4G5-graft aimed at retaining the antigen affinity of the CDR donor while avoiding destabilizing interactions with divergent residues in the acceptor framework. Such destabilizing interactions would either reduce the thermodynamic stability of the graft, or change the loop conformations and reduce the antigen affinity.

## Further analysis of the equilibrium denaturation data

In systems that conform to a two-state equilibrium of unfolding the stability $\Delta \mathrm{G}_{(\mathrm{H} 2 \mathrm{O})}$ of a molecule can be derived from a linear extrapolation to $[D]=0$ of $\Delta \mathrm{G}$, calculated from the equilibrium constant, as a function denaturant concentration.

The tryptophan fluorescence emission spectrum was used to monitor the unfolding of the scFv (Figure S2, Table ST1). While the fluorescence intensity Y is linearly dependent on the fraction of molecules unfolded, the signal-to-noise ratio of this measurement is very poor, since it is highly sensitive to light scattering due to aggregation and to errors in the protein concentration (Figure S3). In addition, the fluorescence intensities of the different tryptophan residues in an scFv change in different directions upon unfolding: the two core Trp L43 and H43 are fully quenched in the native state, their fluorescence increases upon unfolding. In contrast, the fluorescence quantum yield of the two Trp residues H 54 and H139, buried in the interface between $\mathrm{V}_{\mathrm{L}}$ and $\mathrm{V}_{\mathrm{H}}$, decreases upon unfolding, reducing the net change of fluorescence intensity. The net change is thus small.

A more robust probe of the unfolding equilibrium is the wavelength of the emission maximum, $\lambda$ max. Upon unfolding of the protein, the Trp side chains become more solvent exposed, and their emission spectrum is shifted towards longer wavelengths, typically from around 336 nm for a mostly buried Tr to around 350 nm for a fully solvent exposed Tr . However, due to the different fluorescence quantum yield of the native and the unfolded state, $\lambda \max$ is not directly proportional to the ratio of the concentrations of the unfolded and the native species. Monsellier and Bedouelle (2005) derived a correction factor to compensate for this deviation, based on the ratio of the curvatures of the spectra of the native $(\mathrm{b}(\mathrm{n})$ ) and the denatured $\left(\mathrm{b}(\mathrm{u})\right.$ ) protein at their respective $\lambda$ max (Figure S4, Table ST2). If $\Delta \mathrm{G}_{(\mathrm{H} 2 \mathrm{O})}^{\prime}$ is the
value obtained from a two-state fit of $\lambda$ max as a function of denaturant concentration (Figure S5, Table ST3), a better value of the actual $\Delta \mathrm{G}_{(\mathrm{H} 2 \mathrm{O})}$ is obtained by introducing the correction:

$$
\Delta \mathrm{G}_{(\mathrm{H} 2 \mathrm{O})}=\Delta \mathrm{G}_{(\mathrm{H} 2 \mathrm{O})}^{\prime}-\mathrm{RT} \cdot \ln (\mathrm{~b}(\mathrm{n}) / \mathrm{b}(\mathrm{u}))
$$

However, comparing the magnitude of the correction terms ( $0.3-0.4 \mathrm{kcal} / \mathrm{mol}$, Table ST4) to the error range of the parameters of the two-state fit, the correction terms does not make a significant change to the result.

More importantly, we conclude that at least 2 of the 3 constructs do not behave as two-state systems in unfolding. The plots of $\lambda \max$ as a function of denaturant concentration show a marked difference in the slope of the unfolding curves for the different scFv constructs (Figure S5). This indicates that the assumption of a two-state equilibrium of unfolding is wrong. The low m-values derived from the two-state fit for constructs 4G7-wt and 4G7-mut confirm the presence of a hidden intermediate in the unfolding process. While other factors than a hidden intermediate can account for minor differences between the m-values of closely related proteins, they cannot explain the large differences observed between the m -values of 4G7-wt (2.1-3.5 kcal-L/ $\mathrm{mol}^{2}$ ) or 4G7-graft (2.3-2.7 kcal-L/ $\mathrm{mol}^{2}$ ) and of 4G7-mut (5.3-6.9 $\mathrm{kcal} \cdot \mathrm{L} / \mathrm{mol}^{2}$ ). The evidence for the presence of a hidden intermediate and the arguments against alternative explanations (such as e.g. incomplete denaturation at high denaturant concentration) are discussed in the accompanying paper (Honegger et al., 2008) and the Supplemental Materials to that paper available at PEDS online. In addition, the very similar thermal and functional stabilities in native buffer of the three constructs investigated here are not compatible with the large difference in $\Delta \mathrm{G}_{(\mathrm{H} 2 \mathrm{O})}$-values derived from a two-state fit.

## VL-Domain

Residue numbering

## Vн-Domain

Graft
Cond

Figure S1: Summary of residue information relevant to the design of a CDR graft
(a) Residue numbers according to the AHo numbering scheme (Honegger and Plückthun, 2001b) and according to the Kabat (Kabat et al., 1991) numbering scheme. Gaps in the sequence alignment are to be centered on the positions highlighted in yellow to reflect the structural equivalence of the positions with the same residue number between antibodies with different CDR lengths in the AHo scheme. In the Kabat scheme, alignment gaps are accommodated in the positions marked in magenta. (b) CDR boundaries according to Kabat (Kabat et al., 1991), Chothia (Chothia and Lesk, 1987; Al-Lazikani et al., 1997) and IMGT (Lefranc et al., 2003) (c) Comparison of the average solvent accessible surface area in the complex and in the free domains yields information on the average contribution of each residue to interface formation (white: $0 \%$ reduction, yellow: $0-20 \%$, yellow-orange: $20-40 \%$, orange: $40-60 \%$, red-orange: $60-80 \%$, red: $80-100 \%$ ) for the binding of hapten antigens, linear oligomeric antigens and structural epitopes in proteins. The same analysis was performed for residues involved in $\mathrm{V}_{\mathrm{L}} / \mathrm{V}_{\mathrm{H}}$ contacts and contact residues between the variable and constant domains. (d) Average relative side chain accessibility in the isolated domain: The solvent accessible surface of each residue was calculated as percentage of the solvent accessible surface the same residue would have in the context of a poly-Ala peptide in extended conformation, using the program NACCESS (Hubbard and Thornton., 1993). Numeric values were converted to a color code: yellow, $0-10 \%$ accessible, signifies a residue that is fully buried, yellow-green: $10-25 \%$, buried; green: $25-50 \%$, green-blue: $50-75 \%$, semiburied; blue: $75-100 \%$, dark blue: $>100 \%$ exposed, signifies a residue is more exposed than it would be in the context of an extended poly-Ala peptide. Fully buried (core) residues are subdivided into upper core, central core and lower core residues as described in the text. (e) Comparison of the sequences of the acceptor framework, the CDR donor and the graft. Residues that are identical in all three molecules are colored blue, residues that match the sequence of the acceptor framework, cyan, and residues derived from the CDR donor, magenta.

Figure S2: Trp Fluorescence spectra of the three single-chain Fv constructs in different concentrations of $\mathbf{G d m C l} . \mathrm{ScFv}$ were diluted to a final concentration of $0.3 \mu \mathrm{M}$ in $0-5 \mathrm{M}$ $\mathrm{GdmCl}, 0.05 \mathrm{M}$ Tris-HCl, pH 7.2 and incubated overnight at $25^{\circ} \mathrm{C}$. Fluorescence spectra were recorded with an emission wavelength of 280 nm . The spectra were fitted by a Taylor series to the 4th order term as described by Monsellier and Bedouelle (2005) to determine the emission maximum, $\lambda$ max.

Figure S3: Plots of fluorescence intensity against guanidinium concentration. The signal-to-noise ratio is too low to derive reliable thermodynamic parameters from a two-state fit to the intensity as a function of denaturant concentration at any wavelength.

Figure S4: Curvature of the spectra at $\lambda_{\text {max }}$

Figure S5: The wavelength of the fluorescence emission maximum plotted against guanidinium concentration for two independent experiments. The spectra were fitted by a Taylor series to the 4th order term as described by Monsellier and Bedouelle (2005) to determine the emission maximum $\lambda_{\max }$. The plots of $\lambda_{\max } \mathrm{vs}$. $[\mathrm{GdmCl}]$ were fitted by a two-state model (Santoro and Bolen, 1988) (Table ST3). However, as explained above, the low m-value precludes that the system follows a two-state system, as alternative explanations can be excluded. (a) and (b) show the results of two independent experiments, using different batches of protein.

(a) Parameter derived if a two-state model is applied to the data shown in Figure 5 of the paper, based on $\lambda$ max values determined by a Gaussian fit to the spectra
(b,c) Parameter derived from the data shown in Figure S4 (a) and (b). Two independent unfolding curves were measured with different batches of protein. In these experiments, $\lambda_{\max }$ was determined by fitting a Taylor series to the 4th order term to the spectra as described by Monsellier and Bedouelle (2005)
${ }^{1}$ from Honegger et al., (2008)
${ }^{2}$ calculated according to Myers et al., (1995).
